Editors' Introduction

Jones (2000) provided an overview of econometric methods applied in the area of health economics. Since then, there has been a dramatic increase in the number of applied econometric work in health economics, boosted by the availability of large-scale datasets as well as the rapid development of new, advanced econometric techniques. The issues of nonlinearity of models, the presence of individual-level unobserved heterogeneity as well as time and cross-sectional dependencies, among others, make health economics applications an interesting area of research for applied econometricians (Basu & Mullahy, 2013).

The selection of chapters presented in this book illustrates a set of established and emerging econometric techniques. These are often presented within the context of an empirical application, and help gain new insights for tackling health economics studies.

This book should be a valuable reference for academics, applied economists, and postgraduate students in health economics and econometrics, guiding them to the use of some of the advanced econometric methods in health economics.

Summary of the Chapters

Galizzi, Harrison, and Miraldo review and assess behavioral insights and experimental methods for measuring risk and time preferences in health economics, illustrating the most important applications to date on the link between structurally estimated risk and time preferences and health behavior. In particular, the chapter describes the recently advanced behavioral econometrics approach that allows jointly eliciting and structurally estimating risk and time preferences for a broad range of models.

Little is known about perceptions of medical expenditure risks despite their relevance to the demand for health insurance. Yilma, O'Donnell, Mebratie, Alemu, and Bedi provide an estimate of subjective probabilities of future medical expenditure, using survey data on a sample of rural Ethiopians. Such estimates show that the majority of rural Ethiopians sampled are able to provide "logically consistent" responses, and indicate that the cross-sectional variance of realized expenditures, which is often used in applied work to proxy risk exposure, greatly overestimates the risk faced by any single household.

Ziebarth reviews the empirical evidence and econometric methods adopted to study how social insurance causally affects the health of beneficiaries. One complication in studying this empirical problem is that changes in health status are correlated with reductions in labor supply and income, leading to an identification problem. The author reviews the empirical methods for identifying causal effects and examines possible limitations to these methods providing suggestions for future research.

Patients and health professionals often make decisions which involve a choice between discrete alternatives. Econometric methods for modeling discrete choices are reviewed in the chapter by Hole. This chapter reviews the most frequently used discrete choice models in the applied health economics literature, and then introduces more recent developments and extensions, such as scale heterogeneity and attribute nonattendance.

Giuntella and Nicodemo review the recent economic literature on health and migration, a much debated topic given the important implications that migration flows have on the health care systems of receiving countries. The authors highlight the empirical challenges that arise when studying the relation between health and migration, and examine the econometric methods available to address them. In particular, Giuntella and Nicodemo analyze immigrant health trajectories, looking at the process of health convergence between migrants and natives, and pointing at the issue of health selectivity and available methods to address it. The effects of immigration on the demand and supply of health care in destination countries are also explored.

Hoch and Chaussé review econometric methods for analyzing cost-effectiveness data. After linking cost-effectiveness analysis to the net benefit regression framework, the authors show how Seemingly Unrelated Regression and Generalized Method of Moments (GMM) can be applied for cost-effectiveness analysis. The review of the methods is supported by an empirical application where various econometric techniques are employed to explore a cost-effectiveness dataset from a published study, highlighting the potential important role of GMM in the analysis of cost-effectiveness data.

Jones, Rice, and Robone explore the utility of the vignette approach as a method for adjusting self-assessed data for systematic differences in reporting behavior, to improve interpersonal and intercountry comparability. This approach relies on two main assumptions, namely response consistency and vignette equivalence, much debated in the literature. The authors contribute to this literature by evaluating the performance of parametric and nonparametric approaches for adjusting for differential reporting behavior. They focus on physical health data represented by mobility, and compare the distribution of mobility based on self-assessment with that based on the corresponding objective measures. The authors find that both parametric and nonparametric approaches do not satisfactorily address the issue of differential reporting, linking this result to

the problematic assumptions of response consistency and vignette equivalence.

Nicoletti, Salvanes, and Tominey contribute to the literature on the response of parental investments to child's health at birth. The authors highlight the econometric challenges that arise when studying this empirical problem, and in particular the issue of endogeneity of child health. While Instrumental-Variables approach is often adopted in this context, the authors propose a new set of instruments for the child health endowment that are often readily available in a large number of datasets and more credible than those used in existing studies.

Barrenho and Miraldo discuss various econometric approaches for the assessment of the determinants of innovation in the pharmaceutical industry, with a special focus on competing risks duration models. The authors review possible methods to model occurrence of events, and look at potential covariates that have been found to correlate with the likelihood of failure of R&D pharmaceutical projects. They propose for a duration model estimation strategy for assessing the destination of R&D projects.

Medical liability plays an important role in explaining deviations from the optimal use of medical treatments. Bertoli and Grembi review methods for studying the relation between different levels of medical liabilities and treatment selection. The authors examine the theoretical mechanisms underlying such relationship, present existing empirical studies and discuss their limitations, offering indications for future research.

Siciliani reviews the range of models and methods adopted to assess the causal effect of three policy interventions: whether hospital competition and higher hospital tariffs can stimulate quality of health care, and whether nonprofit hospitals provide higher or lower quality than for-profit ones. In addition, this chapter reviews the main results obtained by existing empirical studies offering some indications on how these could be used by policy makers, as well as providing directions for future research.

Effective and efficient use of hospital treatments and services are also the subject of the chapter by Martini and Vittadini. The authors discuss how to exploit administrative data to measure hospital efficiency and relative effectiveness, and they can be used to produce rankings of health care organizations, thus reducing the degree of asymmetric information that typically characterize the health care sector.

Baltagi, Moscone, and Santos review spatial econometrics methods and their application in the area of health economics. In both micro- and macro-health economics there are phenomena that are characterized by a strong spatial connotation. The authors review methods and applications showing how incorporating spatial effects may improve our understanding of issues such as hospital quality, efficiency, or the sustainability of health care expenditure of national and regional health care systems.

Weak and strong forms of cross-sectional dependence are often present in large, aggregate panel data, such as the OECD, country-level health

data set considered in the chapter by Okunade, You, and Koleyni. The authors investigate the relationship among health care expenditure, income, aging population, and international cooperation patents. A voluminous literature has been studying the income elasticity of health expenditure, given its important policy implications for the financing and distribution of health care resources. The authors find the presence of a long run relationship among health expenditure and its determinants, and that per capita GDP (less health expenditure) is the only short run driver of health care expenditure.

In spatial econometric models the neighborhood structure is represented by the so-called spatial weights matrix, usually assumed to be known a priori using information on distance between units, such as the geographic, economic, policy, or social distance. However, in many cases the network is not known (or only partly known), so the interest is not only in quantifying the strength/sign of interactions, but also in the detection of interactions. Moscone, Vinciotti, and Tosetti review graphical modeling techniques for estimating large covariance matrices, useful for estimating networks. The chapter provides a selective survey of different models and estimators proposed by the graphical modelling literature and offers some practical examples where these methods could be applied in the area of health economics.

CHAPTER 1

Experimental Methods and Behavioral Insights in Health Economics: Estimating Risk and Time Preferences in Health

Matteo M. Galizzi, Glenn W. Harrison and Marisa Miraldo

Abstract

The use of behavioral insights and experimental methods has recently gained momentum among health policy-makers. There is a tendency, however, to reduce behavioral insights applications in health to “nudges,” and to reduce experiments in health to “randomized controlled trials” (RCTs). We argue that there is much more to behavioral insights and experimental methods in health economics than just nudges and RCTs. First, there is a broad and rich array of complementary experimental methods spanning the lab to the field, and all of them could prove useful in health economics. Second, there are a host of challenges in health economics, policy, and management where the application of behavioral insights and experimental methods is timely and highly promising. We illustrate this point by describing applications of experimental methods and behavioral insights to one specific topic of fundamental relevance for health research and policy: the experimental elicitation and econometric estimation of risk and time preferences. We start by reviewing the main methods of measuring risk and time preferences in health. We then focus on the “behavioral econometrics” approach to jointly elicit and estimate risk and time preferences, and we illustrate its state-of-the-art applications to health.

Keywords: Behavioral experiments in health; risk preferences; time preferences; randomized controlled trials; technical paper

1.1. Introduction

In the last few years, insights from behavioral economics have gained momentum among health policy-makers. Governments in developed countries have constituted “behavioral insights teams,” within their civil services, including the so-called “Nudge Unit” in the UK Cabinet Office, the behavioral science teams within the UK Department of Health, the NHS, and Public Health England, and analogous initiatives in other governments and international institutions (Dolan & Galizzi, 2014a; Sunstein, 2011).

At the same time, experimental methods have attracted attention among researchers and policy-makers. Most researchers and decision-makers in health economics, policy, and management, however, still implicitly associate experiments with developing countries, where the priorities and organization of health policies and systems are centered around access to care and the outspread of infectious diseases. Almost invariably, these experiments are also viewed as synonymous with “randomized controlled trials” (RCTs).

There is a tendency to reduce the remit of “behavioral” applications to health to “nudges,” to subtle changes in the decision environment or “choice architecture,” that trigger changes in health behavior at an automatic or unconscious level (Galizzi, 2014). We argue that there is much more to behavioral insights and experimental methods in health economics than just nudges and RCTs. We argue this for two reasons.

First, from a methodological perspective the current emphasis on RCTs is misleading because it overlooks the richness of a broad array of experimental methods spanning the lab to the field. The discussion about experimental methods in health economics should be centered around the advantages, disadvantages, and potential scope of the different types of experiments proposed by Harrison and List (2004), each of which could prove useful in health economics. The different types of experiments, including RCTs, should be seen as complementary rather than substitutes. More generally experiments should be seen as complementary to theory and econometrics.

Second, in health economics, policy, and management experimental methods and behavioral insights go beyond nudges and are applied to contexts other than developing countries. Many challenging applications are in high- and middle-income countries, which are redesigning their health systems to address the pressing challenges brought about by aging populations and increased prevalence of noncommunicable diseases.

Why does this focus on RCTs and nudges matter when we are concerned about developments in health econometrics? Advocates of nudges and RCTs often argue that in assessing interventions one should “let the data speak,” that is design an experiment that lets the data speak directly to those wanting policy evaluations. Simple “average treatment effects,” ideally, become just a matter of arithmetic. This is viewed as a positive

thing as it allows policy evaluations that do not depend on econometric assumptions, beyond the basics of randomization. The same agnosticism extends to the use of formal theory. In what follows, however, we will argue that theory, behavioral experiments, and econometrics are complementary methods, rather than substitutes.

We illustrate this point by describing the applications of experimental methods and behavioral insights to one specific topic of fundamental relevance for health research and policy: the elicitation and estimation of risk and time preferences.

Section 1.2 discusses the links between RCTs and the broader range of types of experiment. Sections 1.3 and 1.4 illustrate the use of behavioral experiments in health, focusing on risk and time preferences. Section 1.3 contains reviews of the main methods to measure risk and time preferences in health, while Section 1.4 focuses on the “behavioral econometrics” approach to jointly elicit and estimate risk and time preferences, and illustrates applications to health.¹ Finally, Section 1.5 concludes.

1.2. Randomized controlled trials and experiments in health economics

Many policy-makers tend to automatically associate behavioral experiments in health with RCTs, probably because one of the most influential reports by the UK’s Behavioural Insights Team, when it was still within the Cabinet Office, stressed the need to conduct RCTs to develop public policy (Haynes, Service, Goldacre, & Torgerson, 2012).

This emphasis on the use of RCTs as the exclusive or fundamental experimental method in health economics, policy, and management calls for two conceptual clarifications.

First, health economists are particularly well aware that the use of RCTs in science is not a new development. Modern evidence-based medicine and pharmacology are all based on RCTs, starting from the pioneering work on scurvy by James Lind in 1747, to the first published RCT in medicine by Austin Bradford Hill and colleagues in 1948. Far from novel, the idea of using randomized controlled experiments has been advocated for decades even for policy applications (Burtless, 1995; Ferber & Hirsch, 1978; Manning et al., 1987; Rubin, 1974).

¹ The term “behavioral econometrics” refers to the application of econometric methods to study issues in behavioral economics. Many of the general methods are the same as in economics in general, but often the adaptation to behavioral issues stresses different aspects of general methods. Section 1.4 provides one rich example, the use of multiple experimental tasks and joint, full information estimation of latent preferences. Others include the use of mixture models as illustrated in Harrison and Rutström (2009).

Second, while the term RCT is now widely in vogue in policy circles, it is often used in a quite peculiar way. In the health economics applications in developing countries, the term RCT is typically used to denote large-scale experiments conducted with entire organizations (e.g., hospitals, villages) without necessarily allowing the stakeholders in those organizations to explicitly express their views or their consent to the proposed manipulations. This is a major conceptual difference with respect to RCTs in medicine or pharmacology, where subjects are always explicitly asked to give informed consent prior to take part into RCTs, and allowed to drop out with important ethical, political, and logistical implications. The term “RCT” is therefore conceptually inappropriate and practically misleading in a health economics and policy context, since it conveys the false impression that subjects have been made aware of being part of an experiment and have been consulted and given their consent to it, when actually this may not be the case.

Furthermore, in the current debate, RCTs are often improperly contrasted with theory, structural econometrics, and other empirical methods that do not entail randomization. These contrasts are artificial and misleading because they often overlook the fact that there is currently debate on whether randomized controlled evaluations allow one to draw causality statements about latent causes or effects, particularly welfare effects. There also remains lively debate on the virtues of “atheoretic versus structural” approaches to econometrics (Deaton, 2010; Harrison, 2010, 2013, 2014; Heckman, 2010; Keane, 2010a, 2010b; Leamer, 2010; Harrison & Ross, 2018). Randomization does not require that one should give up theory or standard econometrics, although it does allow one to do so under certain idealized circumstances.

Furthermore, RCTs are only one specific type of experiment. The taxonomy of experiments proposed by Harrison and List (2004) illustrates the diversity of experiments: conventional lab experiments involve student subjects, abstract framing, a lab context, and a set of imposed rules; artefactual field experiments depart from conventional lab experiments in that they involve nonstudent samples; framed field experiments add to artefactual field experiments a field context in the commodity, stakes, task, or information; and, finally, natural field experiments depart from framed field experiments in that subjects undertake the tasks in their natural environment, and subjects do not know that they take part into an experiment.

The main idea behind natural field experiments is equivalent to von Heisenberg’s “uncertainty principle” in physics: the mere act of observation and measurement necessarily alters, to some extent, what is being observed and measured. In key areas for health economics, for example, there may be potential experimenter demand effects, where participants change behavior due to cues about what represents “appropriate” behavior for the experimenter (Levitt & List, 2007); Hawthorne effects, where simply knowing they are part of a study makes participants feel important and improves

their effort and performance (Levitt & List, 2011); and John Henry effects, where participants who perceive that they are in the control group exert greater effort because they treat the experiment like a competitive contest and they want to overcome the disadvantage of being in the control group (Cook & Campbell, 1979).

Moreover, RCTs and other randomized experiments can also be potentially subject to randomization biases. These are sample selection biases related to the fact that knowing that random assignment is in place causes the type of individual participating in a randomized study to differ from participants in other studies in a way that affects inferences about some outcome of interest (Harrison, Lau, & Rutström, 2009; Heckman & Smith, 1995; Kramer & Shapiro, 1984). This type of bias is fundamental to randomized evaluations, assuming that subjects know or even perceive that randomization to treatment is occurring.

Other types of experiments beyond lab, artefactual field, framed field, and natural field experiments are virtual experiments that combine controlled experiments with virtual reality settings (Fiore, Harrison, Hughes, & Rutström, 2009) and lab-field experiments that consist of a first-stage intervention under controlled conditions (in the lab) linked to a naturalistic situation (in the field) where subjects are not aware that their behavior is observed. Lab-field experiments have been used to look at the unintended “behavioral spillover” effects of health incentives (Dolan & Galizzi, 2014b, 2015; Dolan, Galizzi, & Navarro-Martinez, 2015). While not yet applied to health economics contexts, virtual experiments are a promising approach to make trade-offs more salient and vivid in health decision-making.

Virtual experiments and lab-field experiments are part of the growing efforts to bridge the gap between the lab and the field in health economics applications (Hennig-Schmidt, Selten, & Wiesen, 2011; Kesternich, Heiss, McFadden, & Winter, 2013). They are also part of the more general behavioral data linking approach, that is, the linkage of behavioral economics experiments with longitudinal surveys, administrative registers, biomarkers banks, scan data, and other big data sources (Andersen et al., 2016; Galizzi, Harrison, & Miniaci, 2016). Data linkage poses new ethical, practical, and logistical challenges when it seeks to link surveys and behavioral experiments with healthcare registers.

RCT is therefore an inappropriate and misleading term to be used to define behavioral experiments in health, as it does not convey key information on the exact nature, scope, and typology of the experiment at hand. There is no consensus on whether lab or field experiments are superior; both have strengths and weaknesses, and their relative merits have been systematically discussed elsewhere (Bardsley et al., 2009; Harrison, Lau, & Rutström, 2015; Harrison & List, 2004; Levitt & List, 2007). There is not one experiment type for potential health economics and policy purposes; rather, the broad spectrum of different types of experiments spanning the lab to the field can prove useful and complementary.

In fact, the broad spectrum of lab to natural field experiments in the [Harrison and List's \(2004\)](#) sense has already been applied in a range of developed countries and economies in transition contexts to a variety of health economics and policy areas, well beyond “nudges.” For example, lab, artefactual field, framed field, and natural field experiments in health have investigated the effects of different providers’ incentives and the role of altruism in Belgium, Germany, and Norway ([Brosig-Koch, Hennig-Schmidt, Kairies-Schwarz, & Wiesen, 2016](#); [Hennig-Schmidt et al., 2011](#); [Kesternich et al., 2013](#)); the role of different healthcare financing policies in Canada ([Buckley et al., 2012](#)); the choice of health insurance in Germany ([Kesternich et al., 2013](#)); and the impact and the unintended spillover effects of financial incentives for health behaviors in the United Kingdom and the United States ([Dolan & Galizzi, 2014b, 2015](#); [Dolan et al., 2015](#); [Volpp, Asch, Galvin, & Loewenstein, 2011](#); [Volpp et al., 2008](#)). In the next sections, we illustrate the scope and potential of behavioral experiments in health by considering an area of fundamental interest for health economics research and policy: the measurement of risk and time preferences.

1.3. Measuring risk and time preferences in health: a review of methods

From a theoretical perspective, risk and time preferences are fundamental individual characteristics at the core of health behavior and decision-making ([Gafni & Torrance, 1984](#); [Van der Pol, 2011](#)). Empirically, they have been found to associate with a number of health and healthcare behaviors including heavy drinking ([Anderson & Mellor, 2008](#)), BMI ([Sutter, Kocher, Glätzle-Reützel, & Trautmann, 2013](#)), healthy nutrition ([Galizzi & Miraldo, 2017](#)), and the uptake of vaccinations, preventive care, and medical tests ([Bradford, 2010](#); [Bradford, Zoller & Silvestri, 2010](#); [Chapman & Coups, 1999](#)).

Moreover, risk and time preferences directly inform the principles and practices of cost-effectiveness analysis (CEA) and cost-utility analysis (CUA) in healthcare ([Bleichrodt, Wakker, & Johannesson, 1997](#)). In particular, they inform the assumptions beyond the Quality Adjusted Life Years (QALY), the measure of health benefits that are commonly employed in CEA and CUA, and that relies on the popular Standard Gamble (SG) and Time Trade Off (TTO) methods to elicit preferences for hypothetical health states ([Attema & Brouwer, 2012](#); [Bleichrodt & Johannesson, 2001](#)).

Despite such a fundamental role of risk and time preferences in the health context, it is surprising that there is no consensus to date on a “gold standard” measurement methodology. A multitude of different methods have been proposed to measure risk and time preferences in health contexts, which are heterogeneous in terms of underlying theoretical frameworks, methodological features, and links to formal econometric analysis.

A major challenge in converging to a consensus methodology to measure risk and time preferences in health is related to the fact that, to date, the different proposed methods are substantially disconnected. On the one hand, the current methods to measure preferences for health outcomes only entail hypothetical scenarios. On the other hand, all the incentive-compatible methods to measure preferences with real consequences are based on monetary outcomes. From both a conceptual and an empirical point of view, it is unclear whether individual risk and time preferences are stable across the health and the monetary domains (Chapman, 1996). Galizzi, Miraldo, and Stavropoulou (2016) summarize the relatively limited number of studies that compare risk taking across the health and other domains, and find that, despite the broad heterogeneity of methods and frames used in the literature, there is general evidence that there are differences across domains, and that these differences also emerge when real consequences are at stake. The elicitation of risk and time preferences with incentive-compatible methods in the health domain is a promising and challenging task, and a priority in the research agenda of behavioral experimentalists in health.

In Section 1.3.1 we review the main methods to measure risk taking in health, while in Section 1.3.2 we review the main methods to measure time preferences in health. In Section 1.4 we focus on the *behavioral econometrics* approach to jointly elicit and estimate risk and time preferences, and we illustrate its main applications to health.

1.3.1. Measuring risk taking in health

There are six main approaches to measure risk taking in health. The first approach uses insurance market choices to infer underlying risk preferences from different insurance contracts (Barseghyan, Prince, & Teitelbaum, 2011; Einav, Finkelstein, Pascu, & Cullen, 2012).

A second approach uses “risky” health behavior such as smoking, heavy drinking, or not using seat belts as indirect proxies for risk taking (Viscusi & Hakes, 2008; Viscusi & Hersch, 2001). In this behavior-proxy strategy, risk preferences are indirectly inferred from observed behavior rather than being directly measured.

A third approach assumes that risk taking is inherently domain-specific, and should therefore be measured by domain-specific questionnaires such as the Domain-Specific Risk-Taking scale (DOSPERT) (Weber, Blais, & Betz, 2002). A disadvantage of this approach is that risk preferences are not directly measured but are inferred from self-reported engagement in “risky” behaviors.

The fourth approach, a simplified variant of the third, is based on self-assessed willingness to take risk generally and in specific domains using Likert scales (Dohmen et al., 2011). This scale-based, self-assessed approach is simple and scores can be quantitatively compared across

domains. However, the theoretical foundations of this “*direct scaling*” approach remain unclear. In particular, the procedure does not allow associating the different individual choices to specific ranges of risk aversion parameters under a theoretical framework. Moreover, the evidence on how these scores correlate with experimental measures for risk preferences is mixed at best (Galizzi, Machado, & Miniaci, 2016; Szrek, Chao, Ramlagan, & Peltzer, 2012).

Two common features of the last three approaches are that they are not incentive-compatible, in the sense that the measures are merely hypothetical and they entail no real consequence to subjects, and that they involve purely self-reported scale measures rather than explicit trade-offs.

The fifth approach encompasses a family of methods that directly measure risk preferences with tasks involving explicit trade-offs, rather than self-reported scales. Within this trade-off approach a common method is the certainty equivalent (CE) method (Prosser & Wittenberg, 2007; Wakker & Deneffe, 1996). CE questions have also been included in surveys such as the US Health and Retirement Survey, with mixed evidence on their links with other risk preference measures and with risky health behaviors (Anderson & Mellor, 2009). Other methods within this trade-off approach are the probability equivalent method, which is also at the heart of the SG method commonly used to measure utilities of health states, and the gamble tradeoff method.

The final approach to measure risk preferences in health uses incentive-compatible (IC) tests involving real rewards to respondents. A “hypothetical response bias” has been documented in the elicitation of risk preferences, with hypothetical methods showing significantly less risk aversion than methods with real rewards (Harrison, 2006). Since measuring risk preferences in health with real health consequences is challenging, most IC methods offer monetary rewards, rather than health rewards, and compare elicited risk preferences to health behaviors (Anderson & Mellor, 2008).

The most common IC measurement procedures for risk preferences for monetary outcomes are reviewed by Harrison and Rutström (2008) and Charness, Gneezy, and Imas (2013). The multiple price list (MPL) design presents subjects with a series of ordered questions, each reproducing a choice between two lotteries. This method fully accounts for an individual being risk averse, risk neutral, or risk seeking, whereas other methods cannot empirically distinguish between risk neutrality and risk-seeking behavior, and some do not even allow one to discriminate between different degrees of risk seeking. A second major advantage of the MPL method is that it allows the researcher to structurally estimate the underlying risk preferences for a sample of subjects. In particular, the behavioral econometrics approach developed by Harrison and Rutström (2008) and Andersen, Harrison, Lau, and Rutström (2008a) uses Maximum Likelihood (ML) to estimate the risk aversion parameters assuming a range of Expected Utility Theory (EUT) and non-EUT models (Section 1.4.1).

The binary choice battery approach shares these advantages, but also allows the estimation of EUT and non-EUT models of risk preferences at the level of the individual (Harrison & Ng, 2016).

1.3.2. Measuring time preferences in health

Several reviews examine different measures of time preferences (Andersen, Harrison, Lau, & Rutström, 2014; Frederick, Loewenstein, & O'Donoghue, 2002). Here, we focus on its applications to health.

The empirical literature which estimates time preferences can be divided generally into three main groups: research that takes advantage of naturally occurring data; research that uses survey questions; and research utilizing experimental methods.

The first consists of using naturally occurring situations in which individuals must choose between alternatives with differential time dimensions, such that an underlying discount rate can be inferred.

A second approach consists of presenting subjects with a set of survey questions about hypothetical immediate and delayed payouts (e.g., Health and Retirement Survey). These survey questions typically lack real monetary payouts, although attempts have been recently made to link IC experimental tests to household surveys (Galizzi, Harrison & Miniaci, 2016; Tanaka, Camerer, & Nguyen, 2010).

The third approach consists of using experimental methods to assess time preferences for health outcomes (Cairns, 1994; Dolan & Gudex, 1995; Van der Pol & Cairns, 2001, 2008). These methods typically use hypothetical trade-offs. Galizzi, Miraldo, Stavropoulou, and Van der Pol (2016), for example, compare time preferences for hypothetical healthcare outcomes between doctors and their matched patients.

Coller and Williams (1999) seems to be the first incentive-compatible study to assess time preferences for monetary outcomes with real monetary payments. This approach, further developed by Harrison, Lau, and Williams (2002), has become a popular standard method to elicit time preferences with real monetary incentives.

The most general approach is to ask subjects an MPL of binary options between a “Smaller Sooner” (SS) monetary payout and a “Larger Later” (LL) amount, allowing one to estimate structural models of discounting function at the pooled and individual levels. When combined with a task to elicit risk preferences, it allows joint “structural” estimations of risk and time preferences considering a broad range of theoretical models following the ML behavioral econometrics approach. Andersen et al. (2008a) were the first to highlight that time and risk preferences should necessarily be elicited and estimated jointly, by noticing that the level of respondents’ discount rate cannot be inferred without knowing or assuming something about the curvature of the utility function (implied, under EUT, by their risk attitudes). In particular, as explained below, assuming risk neutrality when the

decision maker is actually risk averse implies a significant overestimation of the latent discount rates.

1.4. Jointly eliciting and estimating risk and time preferences: the behavioral econometrics approach

1.4.1. General framework

Using ML, the behavioral econometrics approach allows the joint elicitation and structural estimation of risk and time preferences for a broad range of models, encompassing EUT and non-EUT models for risk preferences, and exponential and nonexponential discounting models for time preferences. Here, we illustrate the approach under EUT. We start by assuming that time preferences are discounted exponentially, and we then consider various models of nonconstant discounting.

Let $U(\cdot)$ denote subjects utility function that is separable and stationary over time, and $D(t)$ a generic discount factor. A subject is then indifferent between SS income option M_τ at time τ and an LL income $M_{\tau+t}$ at time $\tau+t$ (with $t>0$) if and only if the sum of the discounted utilities of receiving the monetary outcome M_τ at time τ in addition to the background consumption ω , and receiving nothing extra at time $\tau+t$ equals the sum of the discounted utilities of receiving nothing in addition to background consumption ω at time τ , and the outcome $M_{\tau+t}$ plus background consumption at time $\tau+t$, i.e.:

$$U(M_\tau + \omega) + D(t)U(\omega) = U(\omega) + D(t)U(M_{\tau+t} + \omega). \quad (1.1)$$

1.4.2. An identification problem

All empirical analyses of discounting models prior to [Andersen et al. \(2008a\)](#) implicitly assumed that the subject is risk neutral, so that Eq. (1.1) could be simply written as:

$$M_\tau = D(t)M_{\tau+t}. \quad (1.2)$$

If, however, the decision maker is not risk neutral, it is evident from an application of Jensen's inequality that the implied discount rate inferred from given choices over SS and LL combinations decreases if $U(M)$ is concave in M . Therefore assuming neutrality when the decision maker is actually risk averse implies an overestimation of the implicit discount rate, due to diminishing marginal utility. More generally, there exists an identification problem in the sense that one cannot infer the level of respondents' discount rate without knowing or assuming something about their risk attitudes (i.e., the value of $U''(\cdot)$). Consequently time and risk preferences should be jointly estimated.

1.4.3. Choice under risk

It is typically assumed that subjects have a Constant Relative Risk Aversion (CRRA) utility function:

$$U(M_\tau, \omega) = (\omega + M_\tau)^{(1-r)} / (1-r), \quad (1.3)$$

where r is the CRRA coefficient and $r \neq 1$. Within this CRRA functional form, $r=0$ implies risk-neutral choices, $r>0$ denotes risk aversion, and $r<0$ implies risk-seeking behavior.

It is often assumed that the utility function is stable over time, and is perceived *ex ante* to be stable over time, so that the same r applies to utility over the lottery payoffs, which are paid immediately, as well as to utility over inter-temporal monetary payoffs, which may be paid with a known delay.²

1.4.4. Individual discounting

The general definition of the discount factor $D(t)$ does not impose any *a priori* restriction on the functional form of the utility function $U(\cdot)$. It can be linear for risk neutrality or nonlinear that has been shown to be of great significance for the estimation of the discount rates. Similarly, the definition of the discount factor does not restrict $U(\cdot)$ to EUT, and in fact several non-EUT specifications can be considered.

One can initially assume that the discount factor takes the exponential (E) specification for $t \geq 0$:

$$D^E(t) = 1 / (1 + \delta)^t. \quad (1.4)$$

In this case, the discount rate is simply $d^E(t) = \delta$, with the key assumption that the rate is constant over time: the percentage rate at which utility today and utility tomorrow is discounted is exactly the same as the rate at which utility in 1 month and utility in 1 month and 1 day is discounted.

The discount factor for the quasi-hyperbolic (QH) specification is defined as:

$$D^{QH}(t) = 1 \quad \text{if } t=0, \quad (1.5a)$$

$$D^{QH}(t) = \beta / (1 + \delta)^t \quad \text{if } t>0, \quad (1.5b)$$

² The question of whether risk preferences are indeed stable over time is directly investigated by Andersen, Harrison, Lau, and Rutström (2008b) in longitudinal artefactual field experiments with representative samples in Denmark, and by Galizzi, Harrison and Miniaci (2016) and Galizzi, Machado and Miniaci (2016) in the United Kingdom.

where $\beta < 1$ implies QH discounting, and $\beta = 1$ collapses to exponential discounting. The defining aspect of the QH specification is that the discount function has a jump discontinuity at $t=0$, and for any $t > 0$ is exactly the same as the E specification. The discount rate for the QH specification is the value $d^{\text{QH}}(t)$ that solves $D^{\text{QH}}(t) = 1/(1 + d^{\text{QH}})^t$, that is $d^{\text{QH}}(t) = [\beta/(1 + \delta)^t]^{(-1/t)} - 1$ for $t > 0$. Thus for $\beta < 1$ a sharply declining discount rate is observed in the very short run, and thereafter the discount rate tends asymptotically to δ as the effects of the initial drop in the discounting factor diminishes. Since it does not vary with the time horizon once $t > 0$, the drop $1 - \beta$ can be viewed as a fixed utility cost of discounting anything relative to the present.

There has been a family of hyperbolic specifications of the discounting function. The simplest specification (H) assumes a discount factor given by

$$D^{\text{H}}(t) = 1/t, \quad (1.6)$$

with discount rate $d^{\text{H}}(t) = t^{(1/t)} - 1$. A flexible Weibull (W) specification is based on the Weibull probability distribution, and is defined as

$$D^{\text{W}}(t) = \exp\left(-\rho t^{(1/\sigma)}\right), \quad (1.7)$$

for $\rho > 0$ and $\sigma > 0$. For $\sigma = 1$ the W specification collapses to the E specification. Consistent with the idea of nonlinear subjective time perception, the parameter σ can be viewed as reflecting the “slowing down” or “speeding up” of time as perceived by the individual. The discount rate at time t in the W specification is $d^{\text{W}}(t) = \exp(\rho t^{(1-\sigma)/\sigma}) - 1$.

1.4.5. Experimental design and experimental tests

In the experiments that jointly elicit and estimate risk and time preferences, subject typically answers two distinct sets of binary questions. At the end of the experimental session, one of the questions is randomly selected to be played for real, and subjects receive real money based on their preferred option in that question.

Time preferences questions are usually repeated both with and without a front-end delay (FED), to capture the possible occurrence of nonconstant discount rates. Although ordered “multiple price lists” have been used to elicit risk and time preferences, more recent applications use unordered batteries of choices.

1.4.6. Econometrics

Following the behavioral econometrics approach, it is possible to directly estimate using ML a structural model of the latent choice process in which

the underlying behavioral parameters defining time and risk preferences are estimated.

In the risk preferences tasks each of the lotteries considered has two possible monetary outcomes M_j , $j=1,2$ with probabilities $p(M_j)$ induced by the experimenter. Under EUT, the expected utility (EU) for lottery i is:

$$EU_i = \sum_{j=1,2} [p(M_j) * U(\omega + M_j)]. \quad (1.8)$$

In the likelihood estimation, a simple stochastic specification is used, which allows some behavioral Fechner errors, and also accounts for “contextual errors”: the EU for each lottery pair is calculated for candidate estimates of the parameters of the utility function $U(\cdot)$, and the ratio:

$$\Delta EU = [(EU_A - EU_B) / \nu] / \mu \quad (1.9)$$

is calculated, where EU_A refers to Option A and EU_B to Option B; ν is a normalizing “contextual” term defined as the maximum utility over all prizes in that lottery pair minus the minimum utility over all prizes in that lottery pair; and μ is the “noise parameter” used to allow some errors from the perspective of the deterministic EUT model. As $\mu \rightarrow 0$ this specification collapses in the deterministic choice EUT model, while as μ gets larger the choice essentially becomes random.

The latent index ΔEU is then linked to observed choices using a logistic cumulative probability distribution function $\Lambda(\Delta EU)$, so that $\text{Prob}(\text{choose lottery A}) = \Lambda(\Delta EU)$. Thus the likelihood of the series of lottery choices, conditional on the EUT and CRRA specifications, depends on r , μ , and the observed choices. Since subjects in the experimental tasks are typically not allowed to express indifference between the two options, the conditional log-likelihood for a generic individual taking part in the experiment is:

$$\ln L^{\text{RP}}(r, \mu; y, \omega, X) = \sum_i [(\ln \Lambda(\Delta EU)) | y_i = 1) + (\ln(1 - \Lambda(\Delta EU)) | y_i = -1)], \quad (1.10)$$

where $y_i = 1$ ($y_i = -1$) denotes the choice of Option B (A) lottery in risk preferences task i . The CRRA r is allowed to linearly depend on a vector X of individual characteristics, $r = r_0 + R'X$ where r_0 and R are (scalar and vector) parameters to be estimated.

A similar specification is used for the discount rate choices. The latent index is given by the difference of the discounted utility of each of the two options, conditional on some assumed discount factor $D(t)$. The likelihood function for these choices is a function of both the risk parameter r and the discount factor $D(t)$. The same stochastic error specification as in the lottery choices can be used, but with a different Fechner error term v . Moreover, in the context of the time preferences tasks, where the choices

are over deterministic outcomes, it is not necessary to apply the “contextual” error correction. Hence, the utility difference between the two options ΔPV is given by:

$$\Delta PV = (PV_A - PV_B)/v, \quad (1.11)$$

where the discounted utility of Option A (PV_A) is:

$$PV_A = D(\tau)U(\omega + M_\tau) + D(\tau + t)U(\omega), \quad (1.12)$$

and the discounted utility of Option B (PV_B) is:

$$PV_B = D(\tau)U(\omega) + D(\tau + t)U(\omega + M_{\tau+t}), \quad (1.13)$$

where τ is equal to 1 month if there is FED, and zero otherwise; and t can be 1, 3, or 12 months, for example. Thus, the likelihood of the discount rate responses, conditional on the EUT, CRRA, and $D(t)$ discount factor being true, depends on r , given the value of the observed choices. The conditional log-likelihood is:

$$\begin{aligned} \ln L^{TP}(r, \mu, D(t), v; y, \omega, X) = & \sum_i [(\ln \Lambda(\Delta PV))|y_i = 1] \\ & + (\ln(1 - \Lambda(\Delta PV))|y_i = -1), \end{aligned} \quad (1.14)$$

where again $y_i = 1$ ($y_i = -1$) denotes the choice of Option B(A) in discount rate task i , and X is a vector of individual characteristics as discussed above.

The joint likelihood of the risk and time preferences responses is then:

$$\ln L(r, \mu, D(t), v; y, \omega, X) = \ln L^{RP} + \ln L^{TP}. \quad (1.15)$$

This expression can then be maximized using standard numerical methods.

The lab experiments that elicit risk and time preferences for student samples typically assume that ω is set equal to zero for all subjects. Experimental elicitations of risk and time preferences with representative samples of the population either set this level equal to average daily income level in the country, or take advantage of the fact of being linked to an asset portfolio from administrative records or to a household survey, to calculate individual-specific values of the background consumption ω (Andersen et al., 2016; Galizzi, Harrison & Miniaci, 2016, respectively).

1.4.7. Applications to health

Even though several studies have looked at the links between risk and time preferences for monetary outcomes and health behaviors (Anderson & Mellor, 2008; Sutter et al., 2013; Szrek et al., 2012), relatively few studies have done so using the behavioral econometrics approach.

In an artefactual field experiment, Harrison, Lau, and Rutström (2010) elicit risk and time preferences of a representative sample of the Danish

population and find no difference in the likelihood of smokers and non-smokers to exhibit hyperbolic discounting, no significant association of smoking with risk aversion among men, and no significant association of smoking with discount rates among women.

In a lab experiment, Galizzi and Miraldo (2017) measure the risk preferences of a convenience sample of students and find that, while there is no association between smoking or BMI with the estimated risk aversion, the latter is significantly associated with the Healthy Eating Index, an indicator of overall nutritional quality.

In another lab experiment, Harrison, Hofmeyr, Ross, and Swarthout (2015) elicit risk and time preferences of a convenience sample of students at the University of Cape Town, and find that smokers and nonsmokers differ in their baseline discount rates, but do not significantly differ in their present bias, risk aversion, or subjective perception of probabilities.

In an artefactual field experiment with a representative sample of the UK population, Galizzi, Machado and Miniaci (2016) assess the external validity of three different measures of risk preferences including the MPL method, and find that the MPL measure of risk aversion significantly predict respondents' consumption of fruit and vegetables, but is not significantly associated with their smoking or drinking habits, nor with the consumption of junk food. By structurally estimating the risk and time preferences of the same UK representative sample, Galizzi, Harrison and Miniaci (2016) find evidence of nonexponential discounting, and look comprehensively at the associations between various estimated models of risk and time preferences and a broad range of health behaviors contained in the linked UK Longitudinal Household Survey.

1.5. Conclusions

Risk and time preferences are of fundamental interest for health economics research and policy since they are the ultimate drivers of a wide range of health-related behaviors and directly inform the principles of cost-benefit analysis moving beyond CEA. We reviewed and assessed the main methods for the measurement of risk and time preferences. We then illustrated how risk and time preferences for monetary outcomes can be elicited using incentive-compatible experimental methods, and how a range of models of risk and time preferences can be structurally estimated using these experimental data. We also described the major applications to date on the links between structurally estimated risk and time preferences and health behavior.

We have demonstrated that there is much more to behavioral insights and experimental methods in health economics than just nudges or RCTs. As we demonstrated for the case of estimating risk and time preferences, tailoring and fine-tuning the broad spectrum of behavioral experiments from the lab to the field to address pressing health policy and research

questions in developed countries is, both methodologically and substantially, one of the most challenging, promising, and exciting areas of applications of experimental methods and behavioral insights to health economics.
